\* Chen, C., Kershaw Jr., J., Weiskittel, A., and McGarrigle, E. 2023. Can a multistage approach improve individual tree mortality predictions across the complex mixed-species and managed forests of eastern North America? Forest Ecosystems 10: 100086.

# Background

- Tree mortality plays a fundamental role in the dynamics of forest ecosystems but is difficult to accurately predict.
- The lack of accuracy is related to tree mortality being rare and stochastic as well as poorly understood processes underlining tree mortality.
- A variety of modeling strategies have been developed to improve tree mortality predictions, of which a multistage approach has mostly been applied in stand mortality models.

# A new multistage approach

## *The stages*

Stage 1: predict annual probability  $p$  that a stand experiences mortality.

Stage 2: predict stand basal area mortality  $m$  ( $\text{m}^2 \text{ ha}^{-1} \text{ yr}^{-1}$ ).

Stage 3: predict annual tree survival probability  $s$ .

# A new multistage approach

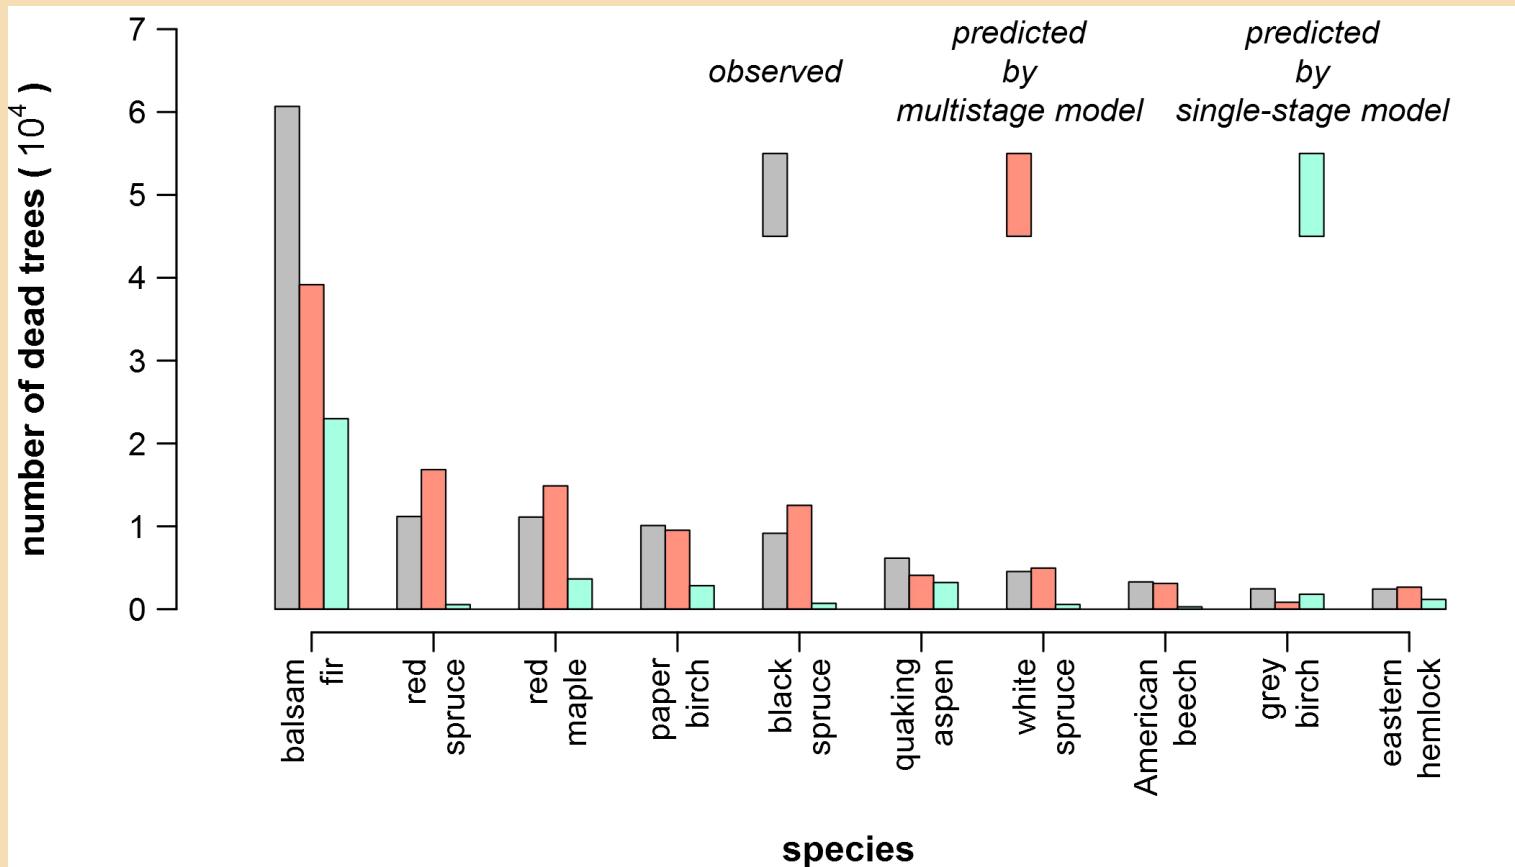

## *The procedure*

1. Multiply stand mortality probability  $p$  by an indicator variable  $I$  such that  $I = 0$  if  $p < v$  and  $I = 1$  otherwise, where  $v$  is an optimized threshold value.
2. Multiply stand basal area mortality  $m$  by  $p \cdot I$
3. trees are ranked by predicted survival probabilities  $s$  in each plot, and trees with the lowest  $s$  are sequentially killed until basal area mortality predicted in the first two stages ( $m \cdot p \cdot I$ ) is achieved.

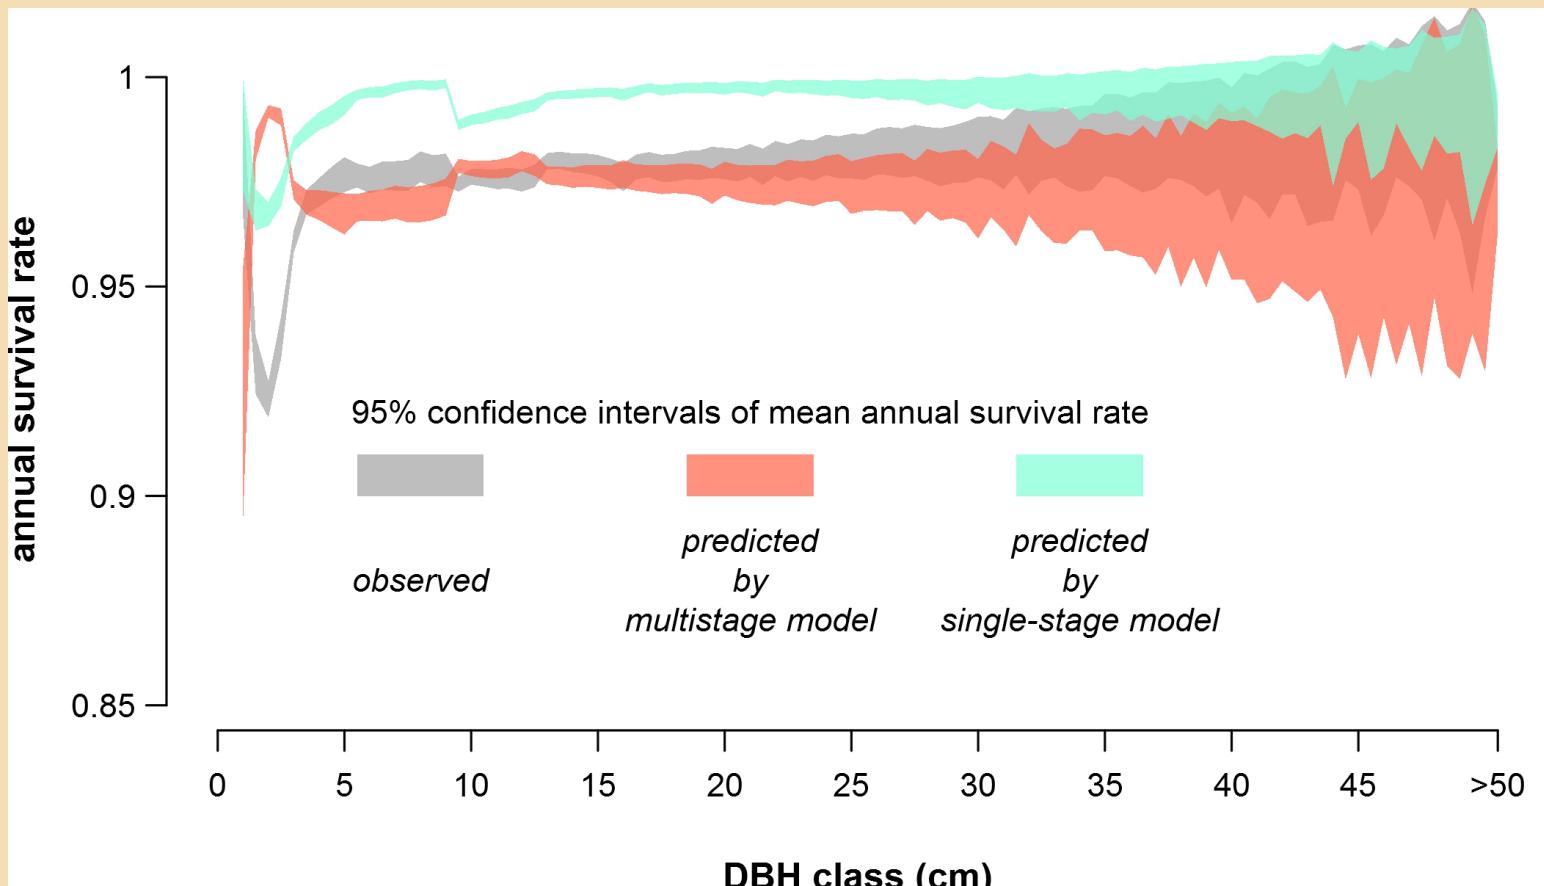

## Comparisons with a conventional tree mortality model

- 9,442 permanent plots across Maine, New Brunswick, Nova Scotia, and Quebec.
- Observed mortality was between  $0.14 \text{ m}^2 \text{ ha}^{-1} \text{ yr}^{-1}$  in Maine and  $0.32 \text{ m}^2 \text{ ha}^{-1} \text{ yr}^{-1}$  in New Brunswick.
- Balsam fir, red spruce, red maple, paper birch, and black spruce had the highest observed mortality of 60,679, 11,183, 11,115, 10,097, and 9,160 trees, respectively.

Individual-tree mortality probability

Stand-level mortality probability

## Takeaways

- The two modeling approaches have similar fit statistics but distinctive model behaviors.
- Both stand basal area mortality and mortality probability models always have nonzero predictions, but the introduction of an indicator variable extends the range of multistage predictions to zero.
- Previous mortality disaggregation techniques always “kill” a portion of a tree by modifying the tree's mortality probability or expansion factor, and errors in the nonzero tree mortality probability predictions are ignored. A ranking system uses ranks in predicted survival probabilities and is more tolerant to errors in predictions.
